RESEARCH MEMORANDUM

PERFORMANCE OF PURE FUELS IN SINGLE J33 COMBUSTOR

II - HYDROCARBON AND NONHYDROCARBON FUELS

By Arthur L. Smith and Jerrold D. Wear

SUMMARY

Performance investigations of 13 fuels - five hydrocarbons, four oxygenated hydrocarbons, and four substituted hydrocarbon-type fuels - were conducted in a single tubular turbojet combustor in order to determine a possible relation between combustor performance and fuel properties. The fuels tested were isoctane, n-pentane, isopentane, 2,2-dimethylbutane, 2-pentene, methanol, propylene oxide, diethyl ether, carbon disulfide, acetone, butylsilane, acrylonitrile, and acrolein.

Combustor temperature rise and combustion efficiency were determined at air-flow rates of 0.6, 0.8, 1.0, and 1.3 pounds per second, inlet-air total temperatures of 40° and 200° F, and a range of heat-input values from about 100 to 750 Btu per pound of air. Combustor-inlet total pressure was held constant at 14.3 inches of mercury absolute. Combustor blow-out limits were determined for the majority of the fuels over this range of test conditions.

At a heat-input value of 250 Btu per pound of air, a tentative correlation was obtained between combustion efficiency and the parameter $u_x/L_v^{1/3}$, where u_x is the maximum burning velocity at atmospheric pressure and temperature and L_v is the latent heat of vaporization at the normal boiling point. The data also indicated an approximate trend toward an increase in maximum temperature rise across the combustor with increase in maximum burning velocity.

The general performance order among the fuels was: butylsilane, carbon disulfide, and propylene oxide - highest; acrolein, acrylonitrile, 2-pentene, diethyl ether, n-pentane, isoctane, and acetone - intermediate; isopentane, 2,2-dimethylbutane, and methanol - lowest.

CB-1

INTRODUCTION

Research is being conducted at the Lewis laboratory to determine design procedures and principles required for the development of high-performance turbojet combustors. One phase of this research program is concerned with a study of the importance of such individual processes as evaporation, ignition, reaction, and quenching that occur in over-all combustion. Because of the complexity of turbojet combustion, one method of studying the individual processes would be to establish a possible relation among combustor performance and selected physical and/or fundamental combustion properties of the fuel. Thus, any relation obtained may indicate the relative importance of the individual processes.

Studies of the relation among combustor performance characteristics and properties of pure fuels are presented in references 1 and 2. In reference 1, combustion efficiency is related to maximum burning velocity and minimum spark-ignition energy. A single pure fuel isoctane (2,2,4-trimethylpentane) was used, and the range in the fundamental combustion properties was obtained by varying the oxygen content of the inlet oxygen-nitrogen mixture. In reference 2, the range in fundamental combustion properties of the fuel was obtained by varying the fuel type. An approximate relation between combustor performance and maximum burning velocity was indicated but, because the range of fuel properties was small, no conclusive relation could be established. Consequently, additional investigations with fuels having a wider range in physical and fundamental combustion properties were recommended.

The full-scale single-combustor performance data reported herein are a continuation of data reported in reference 2. Thirteen pure fuels, including five hydrocarbons, were selected because of their wide range in physical and fundamental combustion properties. The combustor test conditions included one inlet-air pressure, two inlet-air temperatures, and four inlet-air mass-flow rates. The inlet-air pressure condition, 14.3 inches of mercury absolute, was sufficiently low to be considered severe from the standpoint of combustion. The two inlet-air temperatures (40° and 200° F) differed by 160° F. The air mass-flow rate was varied from 0.6 to 1.3 pounds per second, resulting in a considerable range of severity. A variable-area fuel nozzle (similar to the type described in ref. 2) was used in order to minimize variations in fuel atomization characteristics.

The physical and fundamental combustion properties considered were normal boiling point, heat content at the spontaneous ignition temperature, latent heat of vaporization, spontaneous ignition temperature, flammability range, minimum spark-ignition energy, and maximum burning velocity. The combustor performance parameters used to compare the fuels were maximum combustor temperature rise and combustion efficiency at a heat-input value of 250 Btu per pound of air. The combustion

performance characteristics of the fuels are presented, and an attempt to establish a relation between fuel properties and combustor performance parameters is made.

359

FUELS

The fuels in the present investigation represent three classes; (1) hydrocarbon, (2) oxygenated hydrocarbon, and (3) substituted hydrocarbon. Laboratory inspection data for these fuels together with physical data from the literature for the pure materials are presented in table I. The physical data for the pure fuels were compared with laboratory test data in order to obtain the listed estimates of fuel purity. The purity of the fuels was at least 95 mole percent except for 2-pentene, which had a purity of about 93 percent. Some fundamental combustion data for these fuels are also included in table I.

UH-L back

APPARATUS AND INSTRUMENTATION

A diagram of the general arrangement of the single J33 combustor and the auxiliary equipment is shown in figure 1. Air flow to the combustor was measured by a square-edge orifice plate installed according to A.S.M.E. specifications and located upstream of all regulating valves. The combustor inlet-air quantities and pressures were regulated by remote-controlled valves in the laboratory air-supply and exhaust systems. The air supplied to the combustor had a dew point of either -20° or -70° F.

A diagrammatic cross section showing the combustor and its auxiliary ducting, the position of the instrumentation planes, and the location of temperature- and pressure-measuring instruments in the instrumentation planes is presented in figure 2. Thermocouples and total-pressure tubes in each instrumentation plane were located at centers of equal annular area. Construction details of the temperature- and pressure-measuring instruments are shown in figure 3.

The two fuel systems used in the present investigation are illustrated diagrammatically in figure 4. In each system, nitrogen pressure was used to force the fuel from the fuel storage accumulators or tanks to the combustor. The systems were flushed with isoctane and then purged with nitrogen after the completion of each fuel run. This was done in order to free the systems of contaminants and of air.

In the system shown in figure 4(a), valves were installed to permit separate or parallel operation of the accumulators. Rubber bladders

were installed in the accumulators to separate the nitrogen and the fuel, preventing possible dissolution of the nitrogen in the fuel. The fuel-flow rate was determined by means of calibrated rotameters located downstream of the accumulators. This system was used for the following fuels: isoctane; isopentane; n-pentane; 2,2-dimethylbutane; 2-pentene; and methanol. Because of the corrosive nature of propylene oxide, diethyl ether, carbon disulfide, and acetone, the bladders were removed from the accumulators during tests on these fuels.

The system shown in figure 4(b) was designed to permit the measurement of the fuel flow by means of a time - weight-flow method in order to eliminate the necessity of open-air calibration of rotameters for the toxic fuels: acrolein, acrylonitrile, and butylsilane. This system is different from that illustrated in figure 4(a) in that there were no bladders in the fuel tanks, and the tanks could not be used independently of one another. The fuel flow was determined by measuring the time rate of change in weight of the tanks. Small fuel tanks were used instead of the large accumulators in order to decrease the fuel-supply system-tare weight for a more accurate fuel-flow measurement.

A variable-area fuel nozzle was used in this investigation in order to minimize the variation in nozzle pressure drop with change in fuel flow. A detailed description of this fuel nozzle is given in reference 2.

PROCEDURE

The combustor performance of the majority of the fuels was determined at the following inlet-air conditions with inlet-air total pressure held constant at 14.3 inches of mercury absolute:

Inlet-air mass flow, lb/sec	Inlet-air velocity, ^a ft/sec	
	Inlet-air total temperature, °F	
	40	200
0.6	60	79
.8	80	105
1.0	100	132
1.3	130	173

^aBased on combustor maximum cross-sectional area of 0.267 sq ft measured $12\frac{1}{2}$ in. downstream of section B-B (fig. 2).

Tests were limited with acrylonitrile, acrolein, butylsilane, and carbon disulfide because of the small quantity of these fuels available.

The desired combustor inlet-air test conditions were established at a low fuel-flow rate (about 200° F combustor temperature rise), and data recorded when conditions were stabilized. Fuel flow was then increased to obtain increments in combustor temperature rise of about 200° F. This procedure was continued until rich blow-out occurred or the maximum capacity of the facilities was attained. The ignition plug was de-energized during operation.

In order to determine the reproducibility of the test results, iso-octane fuel was investigated periodically over the testing period. In addition to the routine checking of the iso-octane data, the combustion chamber was periodically cleaned to ensure freedom from deposits which might affect performance.

CALCULATIONS

Combustor temperature rise. - The combustor temperature rise was determined as the increase in gas temperature from section B-B to C-C (fig. 2). The temperature at B-B was the average indication of the two iron-constantan thermocouples; the temperature at C-C was the arithmetic average indication of the 16 chromel-alumel thermocouples. The indicated thermocouple readings were taken as true values of the total temperature.

Combustion efficiency. - Combustion efficiency was defined as

$$\frac{\text{Actual enthalpy rise across combustor}}{\text{Heating value of fuel} \times \text{fuel flow}}$$

The equations and charts of reference 3 were used to determine combustion efficiency for the hydrocarbon fuels. Additional information concerning the use of these charts is presented in reference 2. The method, however, is restricted to fuels containing only hydrogen and carbon.

The combustion efficiency for the oxygenated hydrocarbons was determined by assuming the products of combustion to be carbon dioxide and water vapor; for example,

The combustion efficiency for the substituted hydrocarbons was determined by assuming the following reactions to occur:

The enthalpy rise of the oxygenated and substituted hydrocarbon fuels was determined as the difference in the enthalpy of the products of combustion at the exhaust temperature and of the inlet temperature. Enthalpy data used to compute the enthalpy rise are from references 4, 5, and 6; heating values of the fuels are presented in table I (lower heat of combustion) along with physical and fundamental combustion data obtained experimentally and from references 7 to 27.

The inlet-air total-pressure values were obtained from the 12 total-pressure tubes (section A-A, figs. 2 and 3), which were connected to a single manifold.

In order to place the performance of the various fuels on a comparable basis, heat input (product of fuel-air ratio and lower heat of combustion of the fuel) was used in place of fuel-air ratio as one of the independent variables.

RESULTS

Combustor performance data for five hydrocarbon, four oxygenated hydrocarbon, and four substituted hydrocarbon fuels obtained in a single J33 combustor are presented in table II. Figures 5 to 17 present relations among heat input, combustor temperature rise, and combustion efficiency for each of the fuels investigated at each of the various operating conditions. Combustor blow-out points are also noted in these figures.

Throughout the test program periodic checks on the performance of the combustor were made using isoctane as a reference fuel. The deviation in combustion efficiency and combustor temperature rise for various heat-input values is shown in figure 5. These data were obtained over a period of 6 months, during which time the combustor was disassembled several times. The average percentage deviation of the combustion efficiency of individual data points from the curve faired through all the data was ± 1 percent. The maximum deviation of the combustion efficiency was 4 percent. Consequently, differences above 2 percent among fuels may generally be considered as real differences, while differences below 2 percent fall within the reproducibility range. Blow-out points could be checked closely at the time obtained; however, comparable data obtained over a period of time varied to some degree.

The data of figures 5 to 17 indicate, in general, a progressive increase in temperature rise with heat input up to the rich blow-out point. However, at some of the inlet conditions, the maximum temperature rise obtained with isoctane, acetone, and diethyl ether occurred at heat-input values lower than that required for rich blow-out. The heat-input values at the rich blow-out points decreased, in general, with an increase in inlet-air temperature and inlet-air mass-flow rates. Rich blow-out points were obtained with all hydrocarbon fuels (figs. 5 to 9), acetone (fig. 11), and diethyl ether (fig. 12) at all combustor-inlet conditions. For the other fuels, rich blow-out points were not obtained at some combustor-inlet conditions because of limitations imposed by the test facilities. These points are indicated on the figures as facility limited and are identified along with rich blow-out points by an assigned symbol.

Maximum temperature rise tended to increase with increase in inlet-air temperature at the lower air-flow rates. However, at the higher air-flow rates, the reverse of this trend is evident. Maximum temperature rise generally decreased with increase in air-flow rate.

Combustion efficiency, in general, decreased with increases in inlet-air mass-flow rate for all fuels except propylene oxide (fig. 13), acrolein (fig. 14), carbon disulfide (fig. 16), and butylsilane (fig. 17). For these fuels, combustion efficiency remained substantially constant with increases in inlet-air mass-flow rate. An increase in inlet-air temperature improved combustion efficiency slightly for the majority of the fuels at all inlet-air mass-flow rates.

The highest combustion efficiency and combustor temperature rise observed, approximately 97 percent and 2254° F, respectively, were obtained with propylene oxide and butylsilane fuel at a low inlet-air mass-flow rate. This temperature-rise value represents a facility limitation. During tests with butylsilane, flocculent particles, possibly products formed by hydrolysis, were observed in the rotameter. After the completion of tests with this fuel, a collection of these particles was found in the fuel filter. When the combustor was disassembled, a heavy silicon dioxide coating was observed on the fuel nozzle, the combustor, and the exhaust thermocouples. A photograph of the fuel nozzle and combustion chamber showing the silicon dioxide deposits is presented in figure 18. The deposit at the base of the fuel nozzle and on the dome of the liner was a fine powder (fig. 18(a)) in contrast to the coarse granular deposits (fig. 18(b)) observed on the nozzle tip, the inner liner wall, and the exhaust thermocouples (not shown). The combustor-outlet temperature data obtained with this fuel are probably lower than the actual gas temperature because of the insulating effect of the heavy deposits formed on the exhaust thermocouples.

DISCUSSION

The objective of the investigation reported herein was to determine a possible relation between combustor performance and physical or fundamental combustion properties of the fuels. Two representative combustor performance parameters were selected for making comparisons among the fuels. The first parameter chosen was combustion efficiency at a heat-input value of 250 Btu per pound of air, the maximum heat-input value at which data were available for all fuels. Combustion efficiency at a particular heat-input value is related to the fuel consumption of the engine. The second performance parameter, maximum temperature rise through the combustor, is related to the altitude operational limits of the turbojet engine.

3554

Combustion Efficiency

A comparison of combustion efficiencies obtained with each fuel at a heat-input value of 250 Btu per pound of air is presented in figure 19. An increase in inlet-air mass-flow rate and, consequently, air velocity, usually tended to decrease combustion efficiency and to increase the variation in combustion efficiency with fuel type. In general, the fuels providing the highest and the lowest combustion efficiency were butylsilane and methanol, respectively. The differences between methanol and butylsilane varied from approximately 30 to 60 percent at the different operating conditions. The general performance order of the remaining fuels was carbon disulfide, propylene oxide, acrolein, acrylonitrile, 2-pentene, diethyl ether, n-pentane, iso-octane, acetone, isopentane, and 2,2-dimethylbutane. From figure 19, it is evident that the performance order of the fuels changed somewhat with combustor operating conditions; consequently, no single correlation between combustion efficiency and fuel properties is likely to be effective over the entire combustor operating range. It is noted that the high performance fuels were less affected by changes in inlet-air mass-flow rates.

Comparison of combustion efficiency with physical fuel properties. - Some physical properties of the fuel that may be considered to have possible effects on combustor performance are (a) latent heat of vaporization, (b) boiling point of the fuel, and (c) heat content at the spontaneous ignition temperature. An increase in the magnitude in any one of these properties might be expected to reduce the rate of vaporization and, consequently, impede the over-all combustion process. However, comparisons of these properties (see table I) with the combustion efficiencies of the fuels described in the preceding section indicate no consistent relation.

Comparison of combustion efficiency with fundamental combustion fuel properties. - Some fundamental combustion properties of fuels that

may be considered to have possible effects on combustor performance are (1) spontaneous ignition temperature, (2) flammability range, (3) minimum spark-ignition energy, and (4) maximum burning velocity. An increase in flammability range or maximum burning velocity, or a decrease in minimum ignition energy or spontaneous ignition temperature might be expected to effect increases in the rate of the combustion process.

Attempts to relate spontaneous ignition temperature and flammability range with combustion efficiency were unsuccessful. There was a slight trend toward a decrease in combustion efficiency with decrease in flammability range and increase in spontaneous ignition temperature; however, the scatter of the data was greater than could be tolerated for correlating performance.

Maximum burning velocity of fuels, with the exception of carbon disulfide, can be correlated approximately with minimum spark-ignition energy (refs. 7 and 8). Accordingly, if a correlation between combustor performance and maximum burning velocity is obtained, a similar correlation between combustion efficiency and minimum spark-ignition energy would be expected. In view of the greater inherent errors associated with determination of minimum spark-ignition energies, the combustor performance data for the various fuels were considered in terms of the maximum burning velocity.

In figure 20, combustion efficiency at a heat-input value of 250 Btu per pound of air is plotted against maximum burning velocity (cm/sec). The inlet-air mass-flow rate and inlet-air temperature are 1.0 pound per second and 40° F, respectively. Interpolated data from figure 19 are included for butylsilane, acrylonitrile, acrolein, and carbon disulfide. Also included in figure 20 are data from reference 2 for five hydrocarbon fuels and comparable combustion efficiencies of iso-octane obtained from interpolation of data from reference 1. Data of reference 1 were obtained in a turbojet combustor of the same design, operated with varying concentrations of oxygen in the inlet oxygen-nitrogen mixture. The values of maximum burning velocity for iso-octane in various oxygen-nitrogen mixtures were obtained from reference 9.

Deviation of the iso-octane data of the present investigation from the corresponding data from reference 1 might be attributed to the differences in fuel atomization resulting from the use of different fuel nozzles. There is reasonable agreement between the two sets of data and there is a definite trend toward an increase in combustion efficiency with increase in maximum burning velocity.

The data points for carbon disulfide and methanol deviate appreciably from the mean curve of figure 20. Examination of the data of table I indicates that the minimum spark-ignition energy of carbon disulfide and the latent heat of vaporization of methanol differ appreciably from

354

CB-2

the average. No consistent trend in the relative position of the data points of figure 20 with the relative value of minimum spark-ignition energy is evident. However, the data of figure 20 generally indicate that for fuels with approximately the same maximum burning velocity, those fuels with higher latent heats of vaporization give lower combustion efficiency. Accordingly, an attempt was made to correlate combustion efficiency in terms of both maximum burning velocity and latent heat of vaporization. The correlation obtained is shown in figure 21 where combustion efficiency is plotted against the parameter $u_x/L_v^{1/3}$. Here u_x is the maximum burning velocity (cm/sec) at atmospheric pressure and temperature and L_v is the latent heat of vaporization (Btu/lb of air) at the normal boiling point. Interpolated data from figure 19 are included for butylsilane, acrylonitrile, and acrolein at two inlet-air mass-flow rates and air temperature conditions, and for carbon disulfide at one inlet-air mass-flow rate and two inlet-air temperatures. The combustion efficiency data of reference 2 for isooctane, cyclohexane, methylcyclohexane, n-heptane, and benzene are also included in the correlation.

3554

A reasonable correlation of the combustion efficiency data is obtained for the majority of the fuels and operating conditions. However, the parameter $u_x/L_v^{1/3}$ must be regarded as tentative in view of the serious deviation of some fuels from the mean correlation curve at some test conditions.

A comparison of the correlation data of figure 21 with those of figure 20 shows that the modified correlating parameter $u_x/L_v^{1/3}$ (1) improved the correlation of methanol, acrylonitrile, and acetone data; (2) did not improve the correlation of carbon disulfide data; and (3) increased the deviations of 2-pentene and acrolein data. The deviations exhibited by both correlations (u_x and $u_x/L_v^{1/3}$) might be attributed to a number of different factors. The values of u_x were determined at conditions considerably different from those used in the turbojet-combustor tests; the effects of variables such as air temperature and pressure and fuel-air contact time on flame speed varied considerably among the fuels tested. Furthermore, a number of variables that influence the primary-zone mixture conditions were not considered; for example, the effects of physical properties of the fuel on fuel atomization and on spray penetration in the combustor primary zone.

Data presented in reference 10 suggest that the rate-controlling process in the turbojet combustor changes with combustor operating conditions. Similarly, the rate-controlling process might be expected to change with fuel properties; for example, the combustion rate of a low-flame-speed fuel might be limited by its flame speed, whereas the

combustion rate of a high-flame-speed fuel might be limited by its vaporization characteristics. If this is true, considerably more data than are presented herein will be required to establish an adequate correlation between combustion performance and fuel properties.

Maximum Temperature Rise

Comparisons of several physical properties (boiling point, latent heat of vaporization, and heat content at the spontaneous ignition temperature) and fundamental combustion properties (flammability range and spontaneous ignition temperature) with the maximum temperature-rise data of the fuels, presented in figures 5 to 17, indicated that none would satisfactorily predict the relative performance trends obtained.

In figure 22 the maximum combustor temperature rise is plotted against maximum burning velocity at each of the combustor inlet-air conditions investigated. Data are presented only for those fuels for which maximum temperature-rise points were obtained at all combustor inlet-air conditions. Maximum temperature-rise data from reference 2 are included in the figure. With the exception of acetone and 2-pentene, the data indicate a slight trend toward an increase in maximum temperature rise with increase in maximum burning velocity. This trend, which is substantiated somewhat by the limited maximum temperature-rise data obtained with acrolein, acrylonitrile, and propylene oxide, is consistent with the trend reported in reference 2. However, again the scatter of the data is too great to permit a prediction of maximum temperature rise in terms of maximum burning velocity. No consistent trend in the relative position of the data points in figure 22 with the relative value of latent heat of vaporization was found. Accordingly, the parameter $u_x/L_v^{1/3}$ would not provide a satisfactory correlation of the data of figure 22.

CONCLUDING REMARKS

Results of this investigation indicated, in general, that fuels with higher values of maximum burning velocities attained higher combustion efficiency and maximum temperature rise. An approximate correlation of combustion efficiency at a constant heat-input value with maximum burning velocity and latent heat of vaporization was obtained in this investigation; however, serious deviations from the correlation were observed for some fuels at some of the test conditions. These deviations may be attributed to (1) the effects of fuel atomization and primary mixture distribution on combustor performance, or (2) insufficient knowledge of the fundamental combustion characteristics of the fuels at the combustion operating conditions investigated.

2554

CB-2 back

The results of this investigation suggest that no single fuel property or combination of fuel properties will adequately correlate the effect of changes in fuel type on combustor performance over the entire engine-operating range. Both physical and fundamental combustion properties are probably important factors in combustor performance.

3554

SUMMARY OF RESULTS

In order to determine a possible relation among the physical or fundamental combustion properties of fuels, or both, and their combustion performance, investigations of 13 pure fuels were conducted in a single tubular combustor. The following results were obtained.

1. The data indicated an approximate trend toward an increase in combustion efficiency and maximum temperature rise across the combustor with increase in maximum burning velocity.
2. At a heat-input value of 250 Btu per pound of air, a tentative correlation was obtained between combustion efficiency and the parameter $u_x/L_v^{1/3}$, where u_x is the maximum burning velocity at atmospheric pressure and temperature and L_v is the latent heat of vaporization at the normal boiling point.
3. On the basis of combustion efficiency at a heat-input value of 250 Btu per pound of air, the general performance order of the fuels was butylsilane, carbon disulfide, and propylene oxide highest; acrolein, acrylonitrile, 2-pentene, diethyl ether, n-pentane, isoctane, and acetone intermediate; isopentane, 2,2-dimethylbutane, and methanol lowest.
4. Changing inlet-air mass flow and inlet-air temperature altered the sensitivity of combustor performance to changes in fuel type. Increases in air mass-flow rate or decrease in inlet-air temperature generally decreased combustor performance and increased differences in combustor performance among fuels.
